

# Characterization of 30 megabase-long piece of *Tepidisphaera mucosa* genome.

Dmitry Biba

## Introduction

*Tepidisphaera mucosa* is a newly sequenced species of bacteria from terrestrial hot springs of Baikal Lake. The similarity of its genome to its closest relatives is around 80%, which is very low, so it was proposed to be a member of novel order *Tepidisphaerales*. Characterization of such extraordinary genome is challenging, but is crucial for complete description of bacterial diversity ([Kovaleva et al., 2015](#)).

## Materials and methods

I downloaded the piece of *Tepidisphaera mucosa* genome from Skoltech server (mg.uncb.iitp.ru). As a first step, I annotated it with prokka (prokka --outdir annotation\_prokka/ --force data/3.fasta --genus Tepidisphaera --species mucosa ; 3.fasta – the file with the piece of genome). Then I extracted CDSs from the piece of genome using gff-file (output of prokka) and a custom python script (hereafter CPS, available at [https://github.com/Captain-Blackstone/Sk\\_bioinf\\_final\\_project](https://github.com/Captain-Blackstone/Sk_bioinf_final_project), as well as the rest of the materials). To obtain some insight into the function of genes annotated as hypothetical proteins by prokka, I performed a search for conserved domains. To do that I submitted the file all\_proteins\_translated.fasta to Batch-CD search (<https://www.ncbi.nlm.nih.gov/Structure/bwrpsb/bwrpsb.cgi>). This file contains amino acid sequences, also obtained with the help of CPS. The results of Batch-CD search were used to complete prokka annotation: hypothetical proteins were substituted with lists of domains found by Batch-CD where it was possible. To get further insight into the functions of annotated proteins I also attempted to find transmembrane domains in the set of the annotated proteins with the help of TMHMM (<http://www.cbs.dtu.dk/services/TMHMM/>), but no such domains were found (you may see the results in the github repository).

Using gff-file outputted by prokka, I extracted operon structure of the given piece of genome. The set of genes was considered to be an operon if it met 3 conditions: (1) the distance between neighbouring genes was not greater than 150 b.p., (2) all the genes in the set were located on the same strand, (3) the number of genes in the set was greater than two. To assign functions to the found operons we manually inspected literature (mainly wikipedia.org, uniprot.org and domain descriptions in Batch-CD results).

To infer horizontal gene transfer (HGT) I used two approaches. First one was to blast obtained CDSs versus NCBI nt database (I used blastn and tblastx, default parameters, merging their results with CPS; blastn was used initially because it finds not-very-close hits, tblastx was used later, because I realised that if I want to find homology in different orders, I better look at protein sequences than nucleotide ones; results were merged because blastn found some genes tblastx did not manage to) and find the phylum of the closest hit (using <https://lpsn.dsmz.de>, in case of *Candidatus Solibacter* <https://microbewiki.kenyon.edu/> was used). If the phylum was not the same as that of *Tepidisphaera mucosa* (namely, *Planctomycetes*) and e-value was lower than threshold ( $1e-10$ ) HGT was assumed. To verify HGT I built a phylogenetic tree with best blast hits using MEGA6 (Maximum likelihood, default parameters) and considered it to be reliable if the tree was discordant with the real phylogenetic tree (which was obtained from wikipedia, searching for corresponding phyla). The second approach was to measure the deviation of gc-content of a gene from the mean gc-content of a given genome piece. For each gene we measured its gc-content, compared it with the distribution of gc-contents of all the possible regions of the same size in the given piece of genome. If the gene in question resided among 5% of the most deviating regions,

HGT was assumed. One may notice that the problem of multiple testing arises. If Bonferroni correction was applied, no significant genes were found, so this test wasn't used to infer HGT, rather it was used to support the HGT assumption from the previous test. The same procedure was done with whole operons rather than genes, because it is assumed that operons may be horizontally transferred as a distinct entity. All the procedures concerning gc-content were done with the help of CPS.

I used barrnap to find rRNAs in the piece of genome (barrnap data/3.fasta --outseq barrnap/rRNAs), aragorn to find tRNAs (aragorn -t data/3.fasta -o aragorn\_out.txt) and CRISPRCasFinder to find CRISPRCas genes (<https://crisprcas.i2bc.paris-saclay.fr/CrisprCasFinder/Index>). I used antiSMASH to find genes associated with secondary metabolites synthesis (<https://antismash.secondarymetabolites.org/#!/start>).

## Results

### Prokka annotation and conserved domains

36 CDSs were found by prokka, among them 16 hypothetical proteins. Batch-CD search found domains for 11 of 16 hypothetical proteins (the comprehensive list of these domains and their description may be found in the github repository: Hypothetical\_proteins\_annotation\_batch\_CD.txt and Prokka\_annotated\_proteins\_annotation\_batch\_CD.txt). The results of these annotations are presented on Table 1.

## Operon structure

We have detected 3 operons in the given piece of genome (Table 2, Figure 1). The scan through literature revealed that most of genes of the first operon are involved in synthesis of cell wall components: GFKBJCAA\_00001 in taurine synthetase, GFKBJCAA\_00002 in the synthesis of isoprenoid precursors, GFKBJCAA\_00005 in cellulose synthetase. Two of three genes in the second operon (GFKBJCAA\_00010 and GFKBJCAA\_00011) are involved in fatty acids biosynthesis. The genes of the third operon lacked any explicit uniting feature - GFKBJCAA\_00020 is involved in cleavage of TM-domains, GFKBJCAA\_00021 in histidine biosynthesis, GFKBJCAA\_00022 in peptidoglycan biosynthesis and GFKBJCAA\_00023 turned out to be some kind of an exonuclease.

operon	coordinates	genes	possible function
		00001; 00002; 00003; 00004; 00005;	
1	43-5120	00006	cell wall building
2	7892-9890	00009; 00010; 00011	fatty acid synthesis
	16663-		
3	19181	00020; 00021; 00022; 00023	undefined

Table 2. The operon structure of the given piece of genome. In the “genes” column the “GFKBJCAA” prefix of each gene is omitted for the sake of clarity of representation.

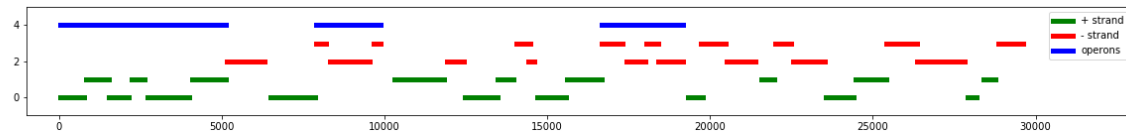

Figure 1. A visualization of genes along the given piece of genome. Green lines represent genes on the “+”-strand, red ones – on “-”-strand. Blue lines represent operons.

## Non-coding RNAs and secondary methabolytes synthesis genes

Aragorn and barrnap have not found any tRNAs or rRNAs in the given piece of genome. AntiSMASH found one gene associated with secondary methabolytes syntheiss – GFKBJCAA\_00029, synthase of all-trans-phytoene – a carotene compound.

## HGT inference

The results of blast search for honologous genes are presented in Table 3. Overall, 20 genes produced significant hits. We considered a gene to be a HGT candidate only if log10 e-value of its hit was less than -10 and the phylum of this hit was not Planctomycetes. There are 6 such genes: GFKBJCAA\_00004, GFKBJCAA\_00010, GFKBJCAA\_00015, GFKBJCAA\_00021, GFKBJCAA\_00022 and GFKBJCAA\_00028.

Prokka ID	method	log10_e_val	Prokka annotation	organism	phylum
GFKBJCAA_00002	tblastx	-14	2-C-methyl-D-erythritol 4-phosphate cytidyltransferase	Planctomycetes bacterium	Planctomycetes

Table 3. The results of blast search in NCBI nt database for genes annotated with prokka.

For two out of six genes – GFKBJCAA\_00015 and GFKBJCAA\_00022 - it was possible to construct phylogenetic trees using best hits from blast (for other sequences there were too little significant hits) (Figures 2 and 3). For GFKBJCAA\_00015 it is apparent that there is no reason to infer HGT, since Target sequence does not cluster within the species produced hits. For GFKBJCAA\_00015 best hits are more various, but wikipedia search reveals that the phylogenetic position of target is consistent with obtained tree (the upper clade on Figure 3 corresponds to terrabacteria – a taxon including Bacteroidetes and Firmicutes phylums, and the lower – to Gracilicutes – a taxon including Chloroflexi and Planctomycetes). So, phylogenetic reconstructions do not support HGT hypothesis.

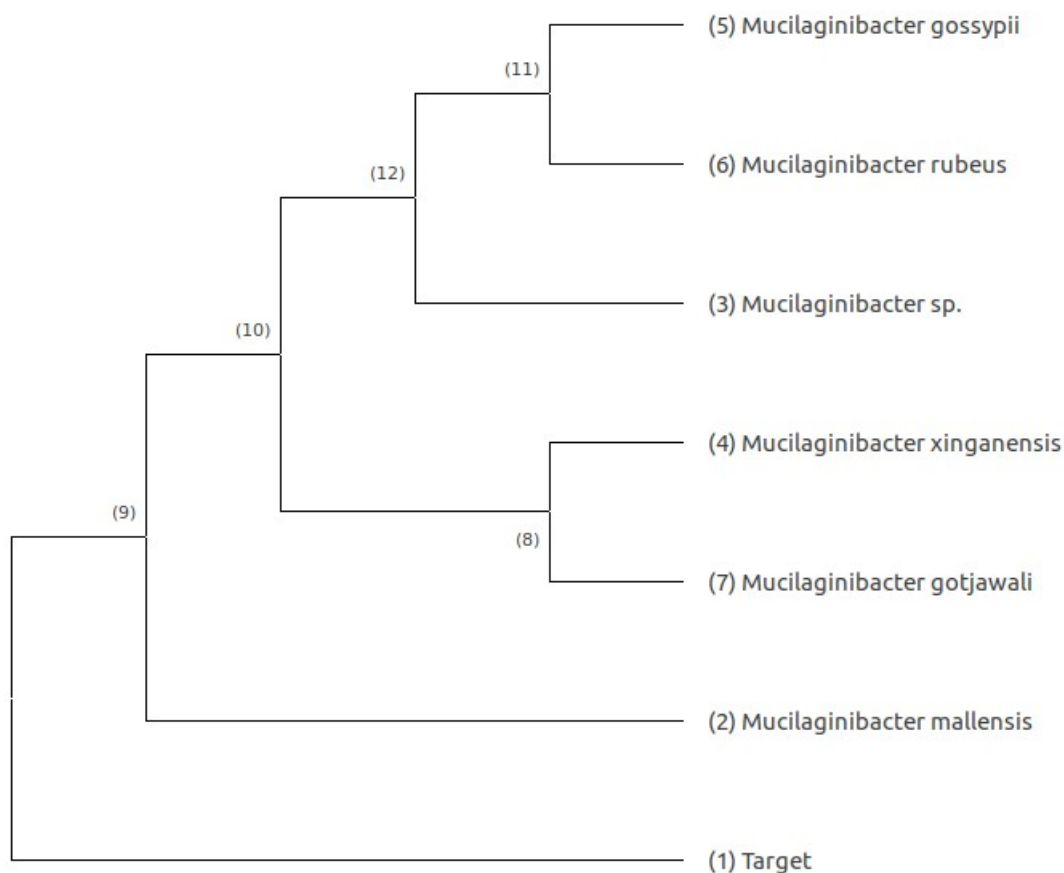

Figure 2. Phylogenetic tree for GFKBJCAA\_00015 constructed using best blast hits.

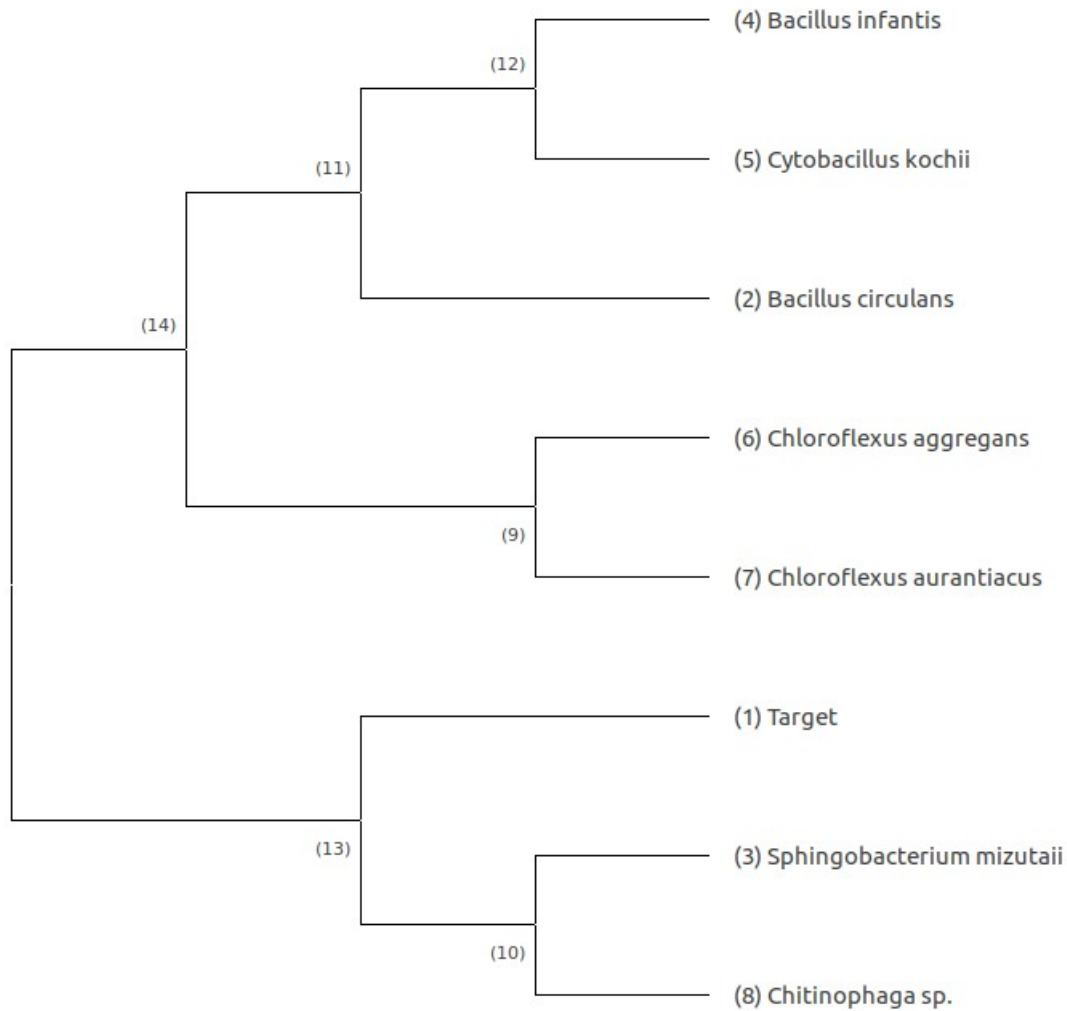

Figure 3. Phylogenetic tree for GFKBJCAA\_00022 constructed using best blast hits.

The results of tests on gc-content deviation for genes are presented in Figure 4 and for operons in Figure 5. Only 2 of genes had notably extraordinary gc-content – GFKBJCAA\_00034 and GFKBJCAA\_00036. However, the effect disappears when applying Bonferroni correction. For the operons no deviations were observed.

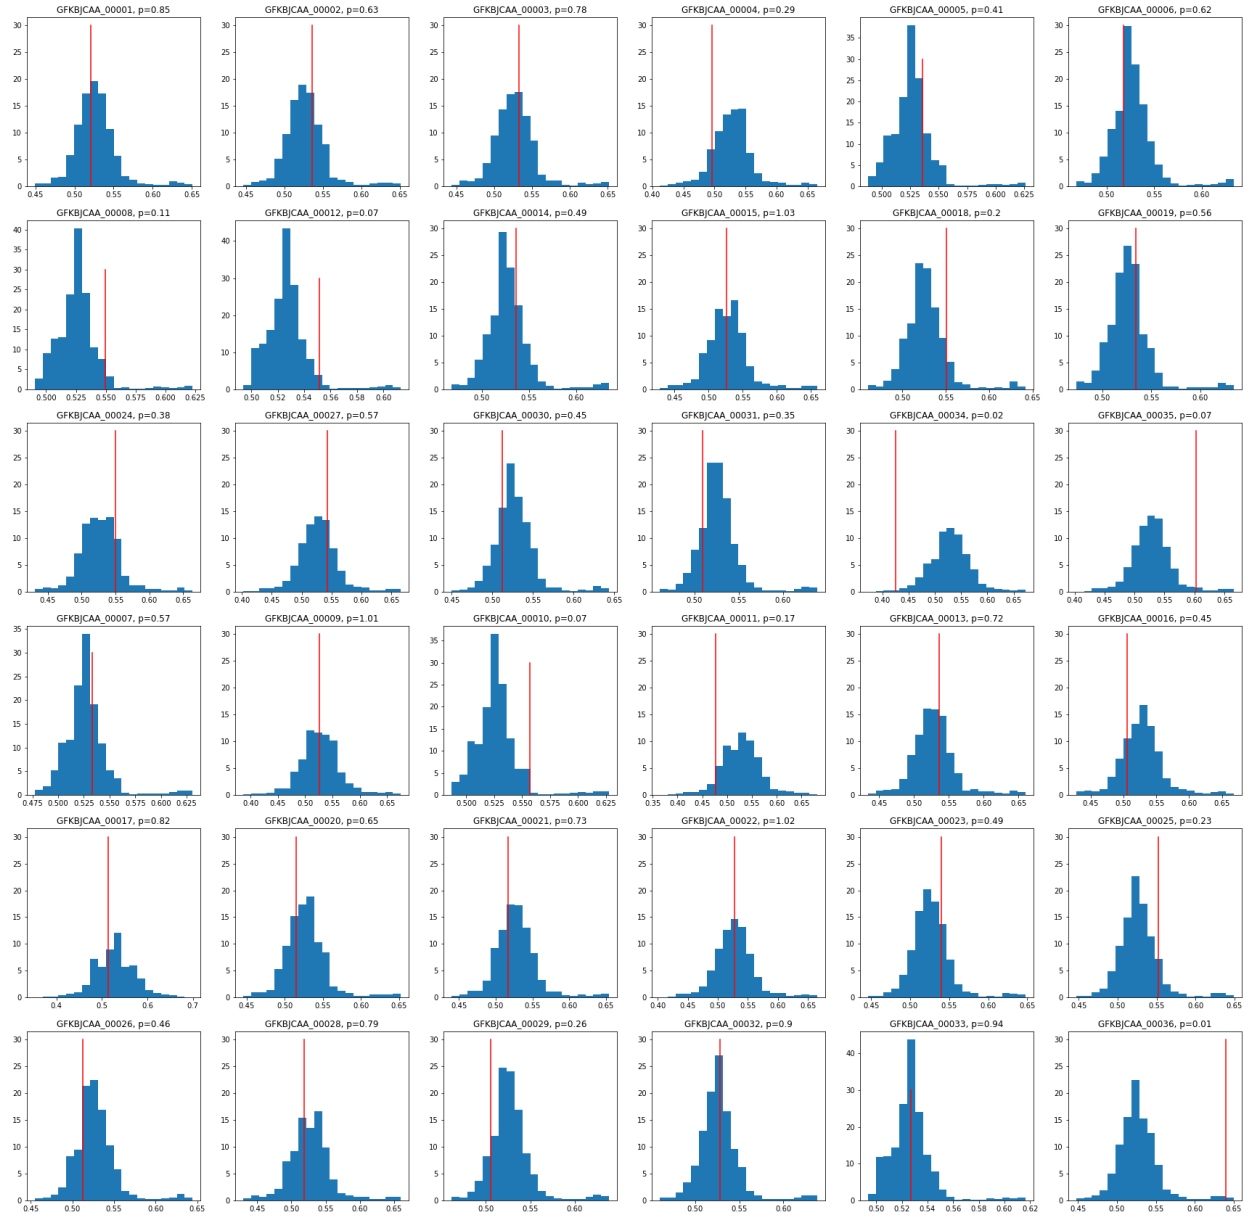

Figure 4. GC-content deviation in prokka annotated genes. Red lines represent gc-content of the gene of interest. Blue histograms represent the distribution of gc-content in all the regions of a given piece of a genome.

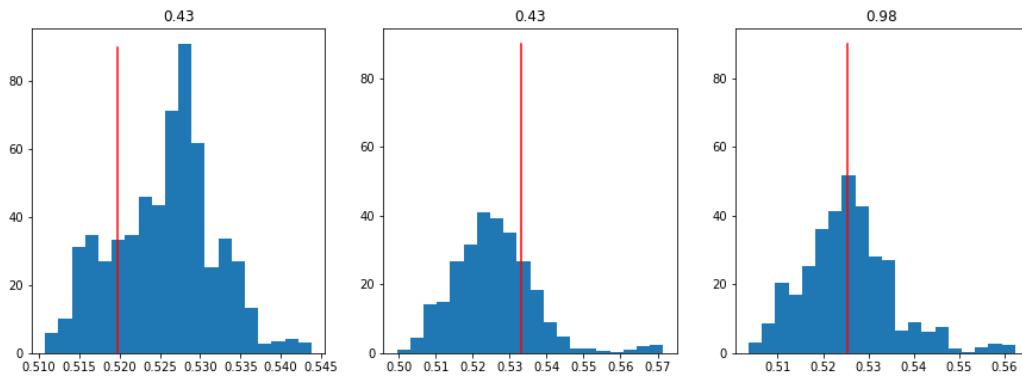

Figure 5. GC-content deviation in operons. The notation is the same as in Figure 2.

## Discussion

I have found 3 operons in the given piece of genome, and managed to assign functions to two of them. The first one contains the following genes: GFKBJCAA\_00001 is involved in taurine metabolism (constituent of cell surface polymers, [Smiley & Brian, 1983](#)), GFKBJCAA\_00002 is involved in isoprenoid precursor synthesis (participating in cell wall synthesis, [Rodríguez-Concepción, 2012](#)) and GFKBJCAA\_00005 contains cellulose synthase subunit and domain associated with exopolysaccharide production genes (which take part in cell wall synthesis, [Haft et al., 2006](#)). The second operon contains GFKBJCAA\_00010, 3-oxoacyl-[acyl-carrier-protein] synthase 2 and GFKBJCAA\_00011, acyl-carrier-protein, both parts of fatty acid synthesis pathways ([InterPro](#) and [wikipedia](#)). It is interesting, that the third one, with unassigned function contains two candidates on HGT out of four genes assigned to this operon, so, it probably is not an operon at all.

The two tests on HGT that I performed yield inconsistent results. One reason I can think of is that in hot springs it is crucial for bacteria to have some precise (and elevated) gc-content in order to not get its DNA melted, so even if gene is horizontally transferred, its gc-content rapidly changes to suite the genomic level. The problem with this interpretation is that genomic average gc-content does not appear to be elevated (it is equal to 0.52), as one would expect from hot spring bacteria. Another explanation might be that gc-content of transferred gene donors was the same as that of *Tepidisphaera mucosa*.

More specifically, GFKBJCAA\_00034 gene, which has very deviant gc-content, produced the best hit in *Lateolabrax maculatus* – a fish, which, probably, hints its HGT origin. The problem here is that this hit is extremely unreliable with e-value ~ 2.5. The rest of the hits produced by this gene have also very high e-value, but all are from various vertebrates. GFKBJCAA\_00036 – the second gene with deviant gc-content – is annotated as hypothetical protein and no conserved domains were found there, so I can't say anything about it.

The genes which produced hits outside the *Planctomycetes* phylum and had the lowest e-value are the most likely candidates to be horizontally transferred. However, if they are parts of the operons, their horizontal origin is questionable, since entire pathways are unlikely to be formed independently and should probably be transferred together. However, only GFKBJCAA\_00004, GFKBJCAA\_00021 and GFKBJCAA\_00022 genes among best HGT candidates are parts of various operons. Among them, GFKBJCAA\_00004 was annotated as a hypothetical protein and the conserved domain found there doesn't have known function, so this gene may even not have a function in this operon. Additionally, the HGT hypothesis for GFKBJCAA\_00022 is not supported by phylogenetic reconstructions. Also, GFKBJCAA\_00021 and GFKBJCAA\_00022, as already has been noted, belong to an operon without an obvious function, which hints that this operon may not be real at all.

## Conclusions

I have described the region of *Tepidisphaera mucosa* genome. I found 36 genes there, at the end only 5 of them lacked annotated function and any domains. I also found 3 operons, 2 of which had more or less distinct function. Lastly, I have found 6 candidate genes which were probably obtained by this bacterium via HGT. I could also build a phylogenetic tree using these sequences and compare it with the species tree to infer HGT, but I didn't have enough time to do this. This may be a future prospect of the current work.

## Supplementary materials

One may find the data I used, the script, all the intermediate files and my journal in the github repository: [https://github.com/Captain-Blackstone/Sk\\_bioinf\\_final\\_project](https://github.com/Captain-Blackstone/Sk_bioinf_final_project)
